Abstract. Predictive maps are increasingly used at all administrative levels for purposes of planning and determining policy priorities. However, current methods yield predictions with limited specificity. It is believed that methodological improvements, such as the use of non-environmental variables, will lead to a better performance of the models. The paper aims to show in what way cultural variables can actually be included in predictive modelling.

Keywords: Predictive modelling; Archaeological heritage management; Cultural variables; GIS

1. Introduction

Predictive modelling is a technique used to predict archaeological site locations on the basis of observed patterns and/or assumptions about human behaviour (Kohler and Parker 1986; Kvamme 1988, 1990). It was initially developed in the USA in the late 1970s and early 1980s where it evolved from governmental land management projects and is still regularly applied in cultural resources management. In the Netherlands, predictive modelling plays an important role in the decision making process for planning schemes on a municipal, provincial and national level.

However, in many other countries predictive modelling is far from being an accepted tool for archaeological heritage management (AHM), and even where it is used regularly, criticism is not uncommon (see e.g. Ebert, 2000; Whitley, in press; van Leusen et al., 2002). Much of this criticism is related to the uncritical application of so-called ‘inductive’ modelling techniques, in which the archaeological data set is used to obtain statistical correlations between the location of archaeological sites and environmental variables such as soil type, slope or distance to water. The performance of these models is in general not very good, partly because of the use of inappropriate statistical techniques, but mainly because of the biased nature of many archaeological data sets and the emphasis on environmental factors, which are easier to model than the more intangible social and cultural factors.

Wheatley (2003) even states that, as predictive modelling doesn’t work very well, it shouldn’t be used at all: “Archaeology should really face up to the possibility that useful, correlative predictive modelling will never work because archaeological landscapes are too complex or, to put it another way, too interesting.” His argument is mainly directed against the use of biased archaeological data sets, that will inevitably produce a positive feedback loop of even more biased data sets, as it is common practice to spend funds for AHM on the areas of ‘high archaeological value’. These areas will become better and better known, whereas the areas that are designated a ‘low value’ on the predictive map will largely be ignored in (commercial) archaeological research.

Verhagen (in press) however shows that the creation of biased data sets is not just a problem of predictive modelling, but a more general characteristic of the way in which archaeological data is collected. Most of the archaeological prospection done is not taking into account statistical sampling theory, and it can be suspected that many survey projects do not even have a strong archaeological hypothesis in mind. We believe that predictive modelling can serve as a means to make explicit the assumptions that are often made concerning the location preferences of prehistoric people. A predictive model should be based on a theory of site location preferences, that can be quantified and tested against (unbiased) archaeological data sets (see also Whitley, in press). It is clear that the cultural component of these theories is at the moment virtually absent in predictive modelling practice. This paper intends to show that it is not impossible to include these variables into predictive modelling, and this will hopefully lead to further research into this subject.

2. Predictive Modelling and Environmental Determinism

The practice of predictive modelling for AHM is, at the moment, environmental deterministic in outlook and design. The predominant use of environmental input variables as archaeological site predictors, such as soil type, groundwater table, distance to open water and the like, has however been criticized on a number of occasions in academic literature.
Archaeological theorists reject an understanding of past human behaviour in purely ecological/economical terms, and argue that social and cognitive factors determine this behaviour to a large extent, and should therefore be additional predictors for the presence and nature of archaeological remains;

- The maximum gain (a measurement of the degree of effectiveness of the predictive archaeological model over a ‘by chance’ model) of current predictive models seems to be about 70% (Ebert 2000, Wheatley 2003), which implies that a significant proportion of archaeological site locations cannot be predicted using purely environmental datasets; therefore, models based on environmental factors alone cannot be adequate tools for the prediction of archaeological site location.

- Unfortunately, social and cognitive factors seem to be difficult to model, and have so far only be studied for a very limited range of questions, based on very specialised data sets (mostly relating to the ritual prehistoric landscapes of Wessex in England e.g. Wheatley 1995; 1996b).

### 3. Cultural Variables: What are They?

It is important to realize that, when we are speaking of cultural variables, we can think of two ways of obtaining them. The first one is to consider them as measurable attributes of the archaeological sample that are not related to an environmental factor. So, instead of measuring for each individual site its soil type, elevation, distance from water and so on, we need to ask which properties of the site itself can be measured. These include properties like site location, size, functional type and period of occupation. These variables are clearly the expression of forms of social behaviour, although the interpretation of the specific behaviour involved may be subject to discussion. For ease of reference, these variables will be denominated cultural variables sensu stricto. In themselves, these variables are not extremely difficult to obtain, but the problems of analysing and interpreting archaeological site databases are manifold and must be addressed before these properties can actually be used for predictive modelling.

The second approach to defining cultural variables is to identify features of the landscape itself that can be interpreted as having cultural significance, such as sacred springs. These can be referred to as cultural landscape variables, and are not necessarily excluded from ‘traditional’ predictive modelling, but often are not recognized as constituting a ‘cultural’ variable. It can, in fact, be argued that all environmental variables have a cultural component, even though the emphasis in traditional predictive modelling is usually on subsistence economy rather than symbolic meanings.

In order to make further use of cultural variables in predictive modelling, it is necessary to transform these variables into continuous variables: for each single variable a value should be available at any location within the study area.

The present practice of predictive modelling is ultimately based on physical properties of the current landscape. For old-fashioned, processual studies, up to the extent which properties of the site itself can be measured. These include properties like site location, size, functional type and period of occupation. These variables are clearly the expression of forms of social behaviour, although the interpretation of the specific behaviour involved may be subject to discussion. For ease of reference, these variables will be denominated cultural variables sensu stricto. In themselves, these variables are not extremely difficult to obtain, but the problems of analysing and interpreting archaeological site databases are manifold and must be addressed before these properties can actually be used for predictive modelling.

In order to make further use of cultural variables in predictive modelling, it is necessary to transform these variables into continuous variables: for each single variable a value should be available at any location within the study area. This is
First Thoughts on the Incorporation of Cultural Variables into Predictive Modelling

4. How to Proceed?

In order to remedy the current situation the following issues should be addressed:

- The identification of cultural variables that are significant for archaeological site location;
- The analysis of the utility of these variables for predictive modelling;
- The development and application of existing and new relevant modelling techniques; and
- The analysis of the performance of predictive models based on cultural variables compared to environmentally based models.

Following the recommendations in van Leusen et al. (2002), we suggest that four promising areas of research should be explored in order to improve on the current use of cultural variables in predictive modelling. These are:

1. A systematic analysis of the archaeological records and their aggregation into culturally meaningful entities

It is necessary to analyse what information can be extracted from existing archaeological databases that can be used in the definition of cultural variables. The aggregation of the archaeological contents of find spots into meaningful archaeological entities is currently not standardized. A possible solution could be to design an expert system that can be used for the classification of find spots. Apart from defining meaningful archaeological entities, the aggregation of multiple find spots into single archaeological sites is an important issue where the utility of the archaeological database for predictive modelling is concerned. Thirdly, a tendency can be observed recently to combine multiple archaeological sites into ensembles, which effectively constitutes a step away from the site level and towards a regional, landscape-based concept of archaeological entities. The main question here is: what types of aggregates can we distinguish, and can these be used as cultural variables?

2. Analysis of the logistic position of settlements

It is anticipated that one of the most important cultural variables that can be used is the logistic position of the archaeological site itself. It has been shown by many researchers that the position of a settlement in a logistic network determines to a large degree its size and duration of occupation (e.g. Durand-Dastès et al. 1998). The development of techniques to analyse the logistic position of settlements can be addressed by looking at recent work in human geography.

3. The continuity of the cultural landscape

The cultural landscape has a historical dimension that strongly influences its use and usability. The existing cultural landscape influences the positioning of new sites. Kuna (1998), for example, mentions the importance of remnants of past landscapes on settlement location choice. Bell et al. (2002) demonstrated how later settlement in their Central Italian study area avoids areas settled in an earlier phase but conforms to paths from that earlier phase. Techniques to perform the long-term diachronical analysis needed for this type of modelling have been developed (e.g. by the Archaeomedes project; van der Leeuw 1998: Favory et al. 2003)

4. Line-of-sight analysis

In hilly areas and with certain site types that have a strong visual component (like burial mounds or megalithic tombs) line-of-sight analysis may be a type of analysis suitable for...
predictive modelling (see van Leusen 2002 chapters 6 and 16). The techniques for performing this type of analysis are well established. It will be noticed that the four research topics mentioned here all focus on cultural variables”. A thorough investigation of the use of cultural landscape variables would primarily involve the development of a decision rule framework that will incorporate the perception of the landscape into predictive modelling. In itself, this is an issue that merits attention, but the establishment of decision rules has always been at the heart of predictive modelling and is covered by a wide range of studies already. It would however be useful to start thinking about ways to model the perception of the landscape, as has been done by Whitley (2000), who tried to model the attractiveness of the landscape for specific (economic) activities of Native American hunter-gatherers (see also Whitley, in press).

5. Conclusions

In a recent article on the use and abuse of statistical methods in archaeological site location modelling Woodman and Woodward (2002) come to the following conclusion: “There has been much criticism of locational studies since they are often based largely on environmental criteria. However, before researchers attempt to incorporate the more intangible social, cognitive, political and aesthetic factors, it would be wise to employ the appropriate statistical techniques required to deal with the complexities which already exist in even the most basic tangible and quantifiable environmental criteria”. Although we do not deny that many statistical problems still exist with regard to predictive modelling, we see no apparent reason why they should receive prime importance in further developing predictive modelling. In fact, the three main issues of statistical methodology, the development of adequate archaeological (and non-archaeological) data sets and the incorporation of non-environmental factors into the models are closely connected, and cannot be tackled in isolation. The papers presented in van Leusen and Kamermans (in press) show that new approaches to predictive modelling are starting to emerge, like exploring the potential of Bayesian statistical methods, using high resolution data for predictive modelling, and looking for ways to better embed predictive models into archaeological heritage management practice, for example by developing risk assessment methods. There is no doubt still a lot to do, and in this respect we have to disagree with Wheatley (2003) who argues that too much money is going into predictive modelling studies. He may be right that funding for GIS-related archaeological projects is mainly going into predictive modelling, but compared to the amount of money spent on all forms of prospection and excavation, investments made in predictive modelling seem relatively modest. Apart from that, investments for a thorough, scientific analysis of predictive modelling have been few and discontinuous. We hope to have demonstrated that incorporating cultural variables into predictive modelling can be done, even though it is impossible to present a comprehensive overview in these few pages. It is up to the scientific community and public institutions to decide if this line of research is worth investing in. However, if the three issues mentioned above (statistical improvements, quality of the archaeological data set and the development of non-environmentally based models) are not tackled in the years to come, predictive modelling will remain to be criticized as a tool that is of dubious scientific quality, and not even capable of providing clear answers on where to spend money for archaeological research.
